In mesoscopic superconducting disks vortices form shell structures as recently observed in Nb disks. We study the dynamics of such vortices, driven by an external current $I_0$, in a Corbino setup. At very low $I_0$, the system exhibits rigid-body rotation while at some critical current $I_{c,i}$ vortex shells rotate separately with angular velocities $\omega_i$. This critical current $I_{c,i}$ has a remarkable nonmonotonous dependence on the applied magnetic field which is due to a dynamically induced structural transition with a rearrangement of vortices over the shells similar to the Coster-Kronig transition in hollow atoms. Thermally activated externally driven flux motion in a disk with pinning centers explains experimentally observed $\omega_i$ as a function of $I_0$ and $T$ and the dynamically induced melting transition.

I. INTRODUCTION

A mesoscopic Corbino disk is a unique system to study the dynamics of self-organized vortex matter in small-size superconductors. The interplay between the vortex-vortex and vortex-boundary interactions in mesoscopic superconductors leads to shape-induced giant vortex states, concentric shells of vortices and symmetry-induced vortex-antivortex “molecules” in mesoscopic squares and triangles. In the Corbino geometry an applied current creates a gradient in the current density and thus the Lorentz force, i.e., introducing a shear driving force between the rings of vortices. This gives us the unique opportunity to study various dynamical effects related to vortex motion, e.g., the transition from elastic to plastic motion, channeling, vortex friction, etc. The dynamics of self-organized vortex matter in mesoscopic disks has many common features to, e.g., atomic matter, charged particles in Coulomb crystals, vortices in rotating Bose-Einstein condensates, magnetic colloids, synthetic nanocrystals, etc., or even large charged balls diffusing in macroscopic Wigner rings and can provide us with a deeper understanding of, e.g., the microscopic nature of friction, transport, magnetic, optical and mechanical properties of various physical and biological systems.

In a Corbino disk, the applied current is injected at the center and removed at the perimeter (see Fig. 1) to induce a radial current density $J$ that decays as $1/r$ along the radius. As a result, vortices near the center of the disk experience a stronger Lorentz force $F_L$ than those near the disk’s edge. For small $J$, the local shear stress is small and the whole vortex pattern moves as a rigid body. Larger $J$ result in a strong spatially inhomogeneous stress that breaks up the vortex solid and concentric annular regions move with different angular velocities. The voltage profiles measured in experiments reflect different dynamical phases (elastic motion, shear-induced plastic slip) of vortex motion. The onset of plasticity in large Corbino disks was theoretically analyzed within a continuous model in Ref. 11. Within molecular dynamics (MD) simulations of interacting vortices at $T=0$, the nucleation and motion of dislocations in the vortex lattice was studied in Ref. 12.

Recently, using the Bitter decoration technique, the direct observation of rings of vortices for mesoscopic superconducting Nb disks was reported. For vorticities $L=0$ to 40, the circular symmetry led to the formation of concentric shells of vortices, similar to electron shells in atoms or in nanoclusters. The analysis of shell filling revealed “magic-number” configurations (MNC) (Refs. 15–17) corresponding to a commensurability between the shells which occurs when the numbers of vortices of each shell have a common divisor.

Here, we study the dynamics of vortex shells in mesoscopic Corbino disks. Our system has the added flexibility that we have several experimentally accessible tuning parameters as, e.g., the driving shear force, the separation between the vortex rings (through the external magnetic field) and the commensurability between the vortex rings (through the relative number of vortices in each ring). In mesoscopic Corbino disks, we reveal a nonmonotonous dependence of the critical current $I_c$ separating two dynamical regimes, a “rigid body” or separate shell rotation, on the magnetic field $h$, and the appearance of dynamical instabilities associated with a jump in $I_c(h)$. We show that this unusual behavior is related to a “structural transition,” i.e., an

(Color online) The Corbino setup: the applied current is injected at the center and removed at the perimeter of the disk to induce a radial current density $J$ (shown by dark blue/dark grey arrows) that decays as $1/r$ along the radius. As a result, vortices near the center of the disk experience a stronger Lorentz force $F_L$ (shown by yellow/light grey arrows) than those near the disk’s edge. The vortices are shown by red-to-yellow/grey-to-light grey tubes and by red/grey spots on the surface. The direction of the external applied magnetic field $H_0$, which is perpendicular to the surface of the disk, is shown by dark yellow/grey arrow.](image-url)
inhomogeneous sheath current density from the center to the edge of the disk and results in the setup is shown in Fig. 1. An external current flows radially to vortex-pin interactions, and which form the MNC and vortex labels, where greek and italic indices refer to vector components i.

II. THEORY AND SIMULATION

We place a Corbino disk which has thickness d and radius R in a perpendicular external magnetic field \( H_0 \). The Corbino setup is shown in Fig. 1. An external current flows radially from the center to the edge of the disk and results in the inhomogeneous sheath current density \( J(r) = \frac{1}{2\pi} \frac{I_{ext}}{r} \), which makes vortices closer to the center feel a stronger force compared to the ones near the edge. The Lorentz force (per unit length) acting on vortex \( i \), \( \Phi_0 \hat{z} \times \hat{\mathbf{r}} \), resulting from the external current is

\[
f^0_i = \frac{\Phi_0}{2\pi} \frac{\hat{z} \times \hat{\mathbf{r}}}{r^2} = \frac{\Phi_0}{2\pi} \frac{r_i \times \hat{\mathbf{z}}}{r_i^2},
\]

where \( \mathbf{r}_i \) is the vortex position, \( \mathbf{r} = \mathbf{r}_i / R \), and \( \hat{\mathbf{z}} \) is the unit vector along the magnetic field direction which is taken perpendicular to the disk. Here \( f^0_i = \Phi_0 / 2\pi \mu_0 R \frac{d^2}{L} = \frac{4\pi \mu_0 H_0^2}{R} \text{ is the unit of force, } I_0 = \mu_0 A L \frac{I_{ext}}{\Phi_0} \), and \( \Lambda = \frac{\lambda^2}{d} \).

In a thin superconducting disk such that \( d < \xi \ll R \), the vortex-vortex interaction force \( f^v_i \) and the force of the vortex interaction with the shielding currents and with the edge \( f^e_i \) can be modelled, respectively, by\(^{18–20}\)

\[
f^v_i = f_0 \sum_{j,k} \left( \frac{r_j - r_k}{|r_j - r_k|^2} - \frac{r_j^2 (r_j - r_k)^2}{|r_j|^4} \right),
\]

\[
f^e_i = f_0 \left( \frac{1}{1 - r_i^2} - h \right) r_i,
\]

where \( h = \frac{\pi R^2 \mu_0 H_0}{\Phi_0} = \frac{(H_0 / 2H_c^2) (R / \xi)^2}{4} \), \( r_i \) is the position of the \( i \)-th vortex, and \( L \) is the number of vortices, or the vorticity. Our numerical approach is based on the Langevin dynamics algorithm, where the time integration of the equations of motion is performed in the presence of a random thermal force. The overdamped equations of motion becomes

\[
f_i = f^a_i + f^v_i + f^e_i + f^\eta_i + f^I_i,
\]

where \( f^a_i = f^0_i \) is the driving force [Eq. (1)], \( f^v_i \) is the force due to vortex-pin interactions, and \( f^e_i \) is the thermal stochastic force, obeying the fluctuation dissipation theorem

\[
\langle f_{a,i}(t) f_{a,j}(t') \rangle = 2 \eta \delta_{a,b} \delta_{\tau,0} \delta(t - t') k_B T,
\]

where greek and italic indices refer to vector components and vortex labels, \( \eta \) is the viscosity. The ground state of the system is obtained by simulating field-cooled experiments.\(^{22}\)

III. VORTEX DYNAMICS IN TWO-SHELL CORBINO DISK

First, we consider the smallest mesoscopic Corbino disk which shows the main physics, and it has \( L = 19 \) vortices which form the MNC (1, 6, 12), as shown in the left-hand inset of Fig. 3. At weak applied magnetic field \( h = 24 \) all the vortices are packed in an almost perfect triangular Abrikosov lattice. (Here we assume a perfect disk with no pinning, and temperature is set to zero after the “annealing” process.) We apply an increasing external current \( I_0 \), and we study the average angular velocity \( \omega \) of vortices in each shell. For small \( I_0 \), the shear produced by the gradient of the Lorentz force is insufficient to break the vortex lattice. It produces only elastic deformations in the lattice which rotates as a rigid body with angular velocity

![Color online](https://example.com/fig2.png)

**FIG. 2.** The angular velocities \( \omega \) (orange/light grey solid circles) and \( \omega \) (blue/dark grey open squares), measured in units of \( \omega_0 = 4\pi \mu_0 H_0^2 / \eta R^2 \), of vortices in the first and second shells, respectively, as a function of applied current \( I_0 \), measured in units of \( \mu_0 A L / \Phi_0 \), for \( L = 19 \) and different magnetic fields \( h \): (a) \( h = 24 \), a rigid-body rotation for \( I_0 < I_1 = 10.4 \); the shells rotate separately for \( I_0 > I_1 \); (b) \( h = 25 \), the critical current decreases, \( I_1 = 6.5 \); (c) \( h = 26.5 \), bistable motion, a second critical current \( I_1 = 7.1 \) appears; (d) \( h = 30 \), the motion stabilizes, and first critical current \( I_1 \) disappears, and critical current \( I'_1 \).
current $I_c$ with increasing applied magnetic field $h$ is summarized in Fig. 3. First, $I_c$ decreases, then instabilities develop in the system which in general are indicative of, and precede, a phase transition. The transition to a second critical field occurs through a bistable state characterized by two critical currents in the system. This unusual behavior can be understood by analyzing the critical current together with the structure of the vortex shells in the region of this “phase transition.” The vortex patterns for magnetic field before (low fields) and after (high fields) the transition are presented on the left-hand side and on the right-hand side insets of Fig. 3. The jump in the critical current is correlated to a “structural transition” in the system where the distribution of vortices over the shells is altered, i.e., there is an intershell vortex transition from a higher to a lower orbit, which is similar to the Coster-Kronig transition in hollow atoms (see, e.g., Ref. 23). This structural transition is accompanied by a local redistribution of the flux inside the disk, or by the appearance of flux jump instabilities, which might have an additional triggering mechanism caused by the viscosity.

We found that this jump in $I_c$ is also observed for other vortex configurations and is generic for vortex structures confined in Corbino disk. For instance, in a disk with $L=22$ it is related to the transition between the states (1,8,13) and (2,8,12) at $h=33.5$. Note that a similar behavior (a jump in the mobility) is also found in the Frenkel-Kontorova model for the locked-to-sliding transition for chains moving on commensurate potentials.24

IV. THERMALLY ACTIVATED EXTERNALLY DRIVEN DYNAMICS IN A CORBINO DISK

Consider now a Corbino disk containing a larger number of vortex shells, e.g., $L=37$ where vortices form three shells. Note that the chosen vorticity allows the triangular-lattice MNC (1,6,12,18) shown in the inset of Fig. 4. As in the above case of two shells, for small $I_0$ the system displays a rigid-body rotation. However, the distance between the inner and the outer shells is larger, and, thus, the Lorentz force gradient results in a stronger elastic deformation of the vortex configuration as compared to the two-shells case. The shear stress is stronger close to the center of the disk, and as a result, the inner shell splits off first at $I_{c23}$, with increasing $I_0$, while second and third shells still rotate with the same angular velocity up to some critical current value $I_{c23}>I_{c12}$ (see Fig. 4).

The three-shell system displays a number of intershell vortex transitions when changing the applied magnetic field. Similar to the case of two shells, a structural “phase transition” occurs where vortices from a higher shell transit to a lower shell when the magnetic field increases. This leads to nonmonotonic dependences of the critical currents $I_{c12}$ and $I_{c23}$ on $h$ and to instabilities in the functions $\omega(I_0)$ at different $h$.

Now we will vary the temperature $T$ and study the thermally activated externally driven dynamics of vortices in the shells. For this purpose, we introduce pinning centers randomly distributed over the disk (for brevity we assume dense narrow pinning centers with maximum pinning force
critical temperature, while higher shells stay locked up to a "second
force which is less than the pinning force \( f_{p0} \) for a vortex in
any shell. At low \( T \) all the vortices are pinned and the shells
do not move. With increasing \( T \), the random-noise force is
added to the (weak) Lorentz force. Intuitively one expects
that vortices in the inner shell, where the Lorentz force is
maximum, will depin first and start to rotate while vortices in
the other shells are still pinned. However, the vortex-vortex
interaction prevents this scenario, and the inner-shell vorti-
ces, if unpinned, become “trapped” by the vortex lattice itself
that leads to an elastic deformation. The vortex-vortex inter-
action locks in the vortex configuration, and when for further
increasing \( T \), the onset of the motion occurs in the form of a
rigid-body rotation (Fig. 5). At some temperature \( T_1 \),
the inner shell splits off and starts moving with a higher angular
velocity, while higher shells stay locked up to a “second
critical” temperature \( T_2 \). The transition from a rigid body to
a separate rotation of shells is called angular melting (i.e.,
the “vortex solid” to “vortex shells” transition). This is a
multistep process which starts when the first shell splits off
(i.e., at \( T_1 \) in our three-shell model) and it finishes when all
the shells rotate independently (\( T \geq T_2 \)), but they keep their
identity and contain a constant number of vortices with well-
defined average radius \( r_i \). The radial melting is associated
with a dissolving of the shells (i.e., the “vortex shells” to
“vortex liquid” transition) and occurs at a higher temperature,
\( T_{M,r} \) (Fig. 5).

This three-shell model explains qualitatively the experi-
mentally observed thermally induced “solid-liquid” melting
transition in a Corbino disk\(^3\) with three probes (see inset to
Fig. 4). Also, the behavior of \( \omega_0(I_0) \) (Fig. 4) is in agreement
with the experimental results. In the experiment, the super-
conducting disk contained a large number of vortices, and
the measurements were done for rings rather than for shells.
To model larger systems, we used a disk with, e.g., 123 vor-
tices forming six shells, and we calculated average velocities
in three rings (each containing two shells). We found that the
results for larger disks are similar to the above three-shell
system, but the radial melting temperature \( T_{M,r} \) is lower,
in agreement with the experiment.

V. CONCLUSIONS

We predict an unusual nonmonotonous behavior of the
critical current for unlocking of the vortex rings with mag-
netic field which originates from a “structural transition”
where a vortex jumps from a higher shell to a lower shell
similarly to the Coster-Kronig transition in hollow atoms.
Pushing the experiments of Ref. 3 into the mesoscopic re-
gime will allow one to detect experimentally the predicted
behavior. The vortex motion in the presence of pinning cen-
ters reveals the onset of a rigid-body rotation, due to ther-
ally activated externally driven flux motion. With increasing
\( T \), the inner shell splits off first and subsequently all the
shells start moving separately. The present numerical study
explains the experiments of Ref. 3, in which vortex velocities
in adjacent layers in a Corbino disk were studied as a func-
tion of \( I \) and \( T \).
