I. INTRODUCTION

Magnetically frustrated systems entail a pattern of interactions that cannot be satisfied simultaneously. These patterns typically involve equivalent antiferromagnetic (AFM) interactions arranged in closed loops with an odd number of bonds, as in a pentagon or a triangle. As one moves around the loop, the spin flips on each bond, and the translation symmetry is violated because the full turn around the loop leads to the inverted spin direction. Therefore, in frustrated systems spins cannot develop a simple collinear AFM order; instead, more complex magnetic ground states appear. Finding appropriate model systems for experimental studies of frustrated magnetism is a long-standing challenge. The availability of model materials is crucial for verifying existing theoretical concepts and expanding the family of frustrated spin systems.

The loops with an odd number of bonds are typically triangular. Planar triangular spin lattices have been widely studied in attempts to achieve a spin-liquid state that lacks long-range magnetic order down to zero temperature. When triangles form corner-sharing tetrahedra instead of tiling the plane, the system enters a so-called spin-ice state that facilitates experimental access to magnetic monopoles. Recent theoretical work puts forward a number of unconventional magnetic ground states that account for main features of the experimental data.

Here, we present the crystal structure, magnetic structure, and thermodynamic properties of the material Bi$_4$Fe$_5$O$_{13}$F. We show that this compound entails a pentagonal arrangement of the spin-$\frac{1}{2}$ Fe$^{3+}$ ions forming the Cairo-type spin lattice. While the magnetic ground state of Bi$_4$Fe$_5$O$_{13}$F is non-collinear and follows expectations for the Cairo spin lattice, the behavior at finite temperatures and the sequence of magnetic transitions are highly unusual and so far unexpected by theory.

The outline of this paper is as follows: In Sec. II, experimental and computational methods are reported. In Sec. III, we present a comprehensive crystallographic investigation and refine the crystal structure of Bi$_4$Fe$_5$O$_{13}$ both above and below the magnetic transitions (Sec. III A). We further study the magnetic ground state (Sec. III B), report thermodynamic properties (Sec. III C), and develop a microscopic magnetic model that accounts for main features of the experimental data (Sec. III D). We conclude our study with a brief discussion and summary (Sec. IV).

II. METHODS

Powder samples of Bi$_4$Fe$_5$O$_{13}$F were prepared by a solid-state reaction of Bi$_2$O$_3$ (99.9% Aldrich), Fe$_2$O$_3$ (nanopowder <50 nm, Aldrich) and BiF$_3$ (99.99% Aldrich). The initial
compounds were weighed in stoichiometric ratios, mixed, rigorously ground, and pressed into pellets. The pellets were placed into alumina crucibles, covered with a lid, and then sealed in quartz tubes under a dynamic vacuum of 10^{-3} mbar. The samples were annealed at 650 °C for 3 h and at 750 °C for 6 h with intermediate regrinding.

X-ray powder diffraction (XRPD) measurements were conducted with a Huber G670 Guinier diffractometer (Cu Kα1 radiation, curved Ge(111) monochromator, transmission mode, image plate). High-resolution synchrotron x-ray powder diffraction (SXPD) data were collected at the ID31 beamline of the European Synchrotron Radiation Facility (ESRF, Grenoble, France) using a wavelength of 0.40006 Å and eight scintillation detectors, each preceded by a Si(111) analyzer crystal. The powder sample was contained in a thin-walled quartz capillary that was spun during the experiment. The temperature of the sample was controlled by a He-flow cryostat (temperature range 10–300 K) and hot-air blower (300–700 K).

Neutron powder diffraction (NPD) data were collected with the high-resolution powder diffractometer HRPT [Paul Scherrer Institute (PSI), Switzerland] at the wavelength of 1.8857 Å with the use of a standard orange cryostat and radiation-type furnace to cover the temperature range from 1.5 to 700 K. Neutron data were corrected for the effects of neutron wavelength and sample absorption. The structure solution was performed with the JANA2006 package.15

Transmission electron microscopy (TEM) investigation was performed with a FEI Tecnai G2 microscope operated at 200 kV. The TEM specimen was prepared by grinding the sample in ethanol and depositing the dispersion on a copper grid covered with a holey carbon film. The sample was analyzed by means of electron diffraction (ED) and high-resolution high-angle annular dark field scanning transmission electron microscopy (HAADF-STEM). The simulated HAADF-STEM images were calculated using the QSTEM 2.0 software.18 The Bi and Fe content has been measured by energy dispersive x-ray (EDX) analysis performed with a Jeol JEM5510 scanning electron microscope equipped with an INCA EDX system (Oxford instruments). More than 50 spectra have been collected in order to obtain a statistically relevant result. Within the experimental error, the measured Bi/Fe = 0.84(6) ratio agrees with the nominal chemical composition.

The magnetic susceptibility of Bi_{4}Fe_{5}O_{13}F was measured with a Quantum Design magnetic properties measurement system (MPMS) superconducting quantum interference device (SQUID) magnetometer in the temperature range 2–600 K in magnetic fields up to 5 T. Heat capacity was measured by a relaxation technique using a Quantum Design Physical properties measurement system (PPMS) in the temperature range 1.8–320 K.

The Mössbauer spectrum was recorded at room temperature (293 K) in transmission mode using a constant-acceleration Mössbauer spectrometer with a nominal 2.02 GBq^{57}Co source in a 6 μm Rh matrix (conventional source). The velocity scale was calibrated relative to a 30 μm α-Fe foil using the positions certified for the National Bureau of Standards standard reference material no. 1541; a line width of 0.30 mm/s for the outer lines of α-Fe was obtained at room temperature. The spectrum collection time was 10 days. The Mössbauer spectrum was fit using the MOSSA software package.19

The electronic structure of Bi_{4}Fe_{5}O_{13}F was calculated within the density functional theory (DFT) framework using the FPLO code20 and the Perdew-Wang parametrization of the exchange-correlation potential.21 The symmetry-irreducible part of the first Brillouin zone was sampled with a k mesh of 72 points for the unit cell with 92 atoms. Strong correlations in the Fe 3d shell were treated by the DFT + U procedure with a Coulomb repulsion U = 7 eV and Hund’s exchange J = 1 eV.22 Magnetic couplings were evaluated by mapping total energies of collinear spin configurations onto the Heisenberg model:

\[ \hat{H} = \sum_{\langle ij \rangle} J_{ij} S_i S_j, \]

where the summation is over all bonds \( \langle ij \rangle \), and exchange integrals \( J_{ij} \) are the coupling energies per bond.

III. RESULTS

A. Crystal structure

X-ray powder diffraction investigation reveals a single-phase Bi_{4}Fe_{5}O_{13}F material with a tetragonal unit cell with lattice parameters \( a = 8.303\ 18\ (5) \text{ Å}, \ c = 18.0640\ (1) \text{ Å}, \) and the space group P4_2/mbc or its acentric subgroup P4_2bc. The electron diffraction patterns of Bi_{4}Fe_{5}O_{13}F (Fig. 2) confirm the unit cell and space symmetry. The structure solution was performed in the centrosymmetric P4_2/mbc space group with direct methods providing the positions of all cations and part of the anions in the unit cell. The missing anions were located using difference Fourier maps. The resulting structural model was refined against the SXPD data at the temperatures of 10, 298, and 673 K and against the NPD data at temperatures of 1.5, 300, and 700 K.23 A magnetic contribution was taken into account for the refinement of the crystal structure from the NPD data collected at \( T = 1.5 \text{ K} \) (see details in Sec. III B). Oxygen and fluorine anions cannot be distinguished reliably from either x-ray or neutron powder diffraction. Therefore, the
assignment of the fluorine position at 4b (0,0,1/4) is based on bond-valence-sum (BVS) arguments.

Bond-valence-sum arguments strongly favor a complete ordering of the O and F anions. The F\(^-\) anions linked to four Bi cations acquire a BVS of 0.91 (2), which is close to their nominal valence. For the O\(^2-\) anions occupying this position, the BVS would be as low as 1.20 (2), thus demonstrating a strong and unrealistic underbonding. The anion ordering is additionally supported by the room-temperature Mössbauer spectrum that is consistent with only two distinct coordination types of Fe\(^{3+}\) cations (see below).

The refinement of the low-temperature diffraction data resulted in low atomic displacements parameters (ADPs) for all atomic positions. However, at and above room temperature high ADPs of F1 and O1 indicated possible displacements of these atoms. Indeed, the displacements of F1 and O1 from their special positions reduced the ADPs. This effect is mostly of dynamic nature, because at low temperatures the displacements are suppressed. The O1 and F1 displacements observed at high temperatures may be driven by subtle adjustments of interatomic distances and coordination (see BVS analysis in the Supplemental Material\(^{23}\)), although further studies of the local structure would be necessary to fully elucidate this issue. We have also checked the possibility of symmetry lowering. The refinement in the acentric group \(P4_2bc\) neither eliminated the disorder, nor reduced the reliability factors. Electron diffraction patterns clearly demonstrate the presence of glide planes perpendicular to the \(a\) and \(b\) unit cell axes, as well as perpendicular to the diagonals of the \(ab\) face. Therefore, any further symmetry reduction can be safely excluded.

The crystallographic information for Bi\(_4\)Fe\(_5\)O\(_{13}\)F at room temperature is summarized in Tables I and II. Further details on the structure refinement and crystallographic data at \(T = 1.5\) and 700 K are given in the Supplemental Material.\(^{23}\)

The crystal structure of Bi\(_4\)Fe\(_5\)O\(_{13}\)F is illustrated in Figs. 3(a)–3(c). It is built of infinite chains of edge-sharing FeO\(_6\) octahedra running along the \(c\) axis and comprising two Fe positions: Fe1 and Fe3 (Fig. 3). The Fe2 atoms form pairs of corner-sharing FeO\(_4\) tetrahedra that link the octahedral chains into a framework. These links repeat at every third FeO\(_6\) octahedron of the chain, thus creating large cavities in the framework. The cavities are occupied by the fluorine-centered tetrahedral Bi\(_4\)F groups.

The structure of Bi\(_4\)Fe\(_5\)O\(_{13}\)F viewed along the \(c\) direction immediately reveals the pentagonal arrangement of the magnetic Fe\(^{3+}\) cations [compare Fig. 3(c) and Fig. 1(a)]. While in Bi\(_2\)Fe\(_4\)O\(_9\) similar pentagonal planes are directly stacked on top of each other, Bi\(_4\)Fe\(_5\)O\(_{13}\)F demonstrates a more peculiar stacking, with the pentagonal planes interleaved by the FeO\(_6\) octahedra [Fig. 3(a)].

The Bi\(_4\)Fe\(_5\)O\(_{13}\)F crystal structure has been validated by HAADF-STEM imaging along the [001] and [100] directions (Fig. 4). In HAADF-STEM, the brightness of a dot corresponding to the projection of an atomic column roughly scales as \(Z^n\) (1.5 < \(n\) < 2), where \(Z\) is the average atomic number along the column. Therefore, Bi-bearing atomic columns appear as the brighter dots and form the most prominent contrast in the image. The insets in Fig. 4 show HAADF-STEM images calculated using the refined atomic positions. The good agreement between the experimental and calculated images justifies the structure solution.

The room-temperature Mössbauer spectrum for Bi\(_4\)Fe\(_5\)O\(_{13}\)F\(^{23}\) can be decomposed into two paramagnetic doublets, contributing to 57 (4)% (doublet I) and 43 (4)% (doublet II) of the total absorption area. Mössbauer parameters, such as center shift (CS) and quadrupole splitting (QS), are as follows:

(1) Doublet I: CS = 0.428 (9) mm/s, QS = 0.39 (2) mm/s;
(2) Doublet II: CS = 0.19 (1) mm/s, QS = 0.65 (2) mm/s.

The CS values for both doublets provide evidence that all iron is in the Fe\(^{3+}\) state.\(^{24,25}\) The CS of the doublet I is consistent with Fe\(^{3+}\) in an octahedral coordination.\(^{25}\) The significantly smaller CS of the doublet II is in agreement with

<sup>a</sup>Reduced occupancy factor: *g*(O1) = $\frac{1}{2}$.

<sup>b</sup>Reduced occupancy factor: *g*(F1) = $\frac{1}{4}$.

The peculiar non-collinear antiferromagnetic structure of Bi<sub>4</sub>Fe<sub>5</sub>O<sub>13</sub>F is shown in Fig. 5. All magnetic moments are confined to the <i>ab</i> plane. The order along the octahedral chains is ferrimagnetic, with two parallel magnetic moments on the neighboring Fe1 atoms, and an opposite moment on Fe3. The direction of these moments is close to [110] and rotates by 90° between neighboring chains, so that the moments in second-neighbor chains are opposite and cancel each other. The magnetic moments of the Fe2 atoms are ~4.2° off the 100 direction and form an AFM configuration within each Fe2O<sub>7</sub> dimer (Fig. 5).

The temperature evolution of the magnetic reflections is nonmonotonic and pinpoints at least two additional magnetic transitions that follow the initial AFM ordering at *T*<sub>N</sub> = 178 K (Fig. 6). The transition at *T*<sub>1</sub> ≈ 62 K is manifested by abrupt intensity variations: the reflections with even <i>I</i> rapidly vanish, whereas the intensities of the reflections with odd <i>I</i> notably increase. The second transition at *T*<sub>2</sub> ≈ 71 K manifests itself by the vanishing of the $\frac{3}{2}$ 0<i>I</i>, <i>I</i> = 2<i>n</i> reflections. The two magnetic transitions below *T*<sub>N</sub> are well in line with the results of thermodynamic measurements (Sec. III C). These transitions are likely accompanied by drastic changes in the magnetic structure. Details of this complex and intriguing magnetic behavior should be addressed in future studies.

### C. Thermodynamic properties

Magnetic susceptibility of Bi<sub>4</sub>Fe<sub>5</sub>O<sub>13</sub>F reveals an overall antiferromagnetic behavior (Fig. 7) in agreement with the antiferromagnetic, albeit non-collinear spin arrangement,
FIG. 3. (Color online) Crystal structure of Bi$_4$Fe$_5$O$_{13}$F: (a) [010] projection, (b) [001] projection, (c) Cairo pentagonal lattice of the Fe atoms. FeO$_6$ octahedra and FeO$_4$ tetrahedra are shown in blue and yellow, respectively. The Bi, F, Fe, and O atoms are drawn as large orange, small light green, medium green, and small blue spheres, respectively.

pinpointed by neutron diffraction. The field dependence of the susceptibility should be ascribed to a tiny amount of a ferromagnetic impurity. Magnetization loops measured at constant temperature do not show any clear signature of a remnant magnetization or hysteresis (Fig. 8, top).

Above 300 K, the susceptibility follows the Curie-Weiss law:

\[ \chi = \frac{C}{T + \theta}, \]

with $C = 3.59(3)$ emu K/(mol Fe) and $\theta = -380(10)$ K (Fig. 8, bottom). The resulting Curie constant corresponds to an effective magnetic moment of $\mu_{\text{eff}} = 5.4\mu_B$, in reasonable agreement with $5.92\mu_B$ expected for the spin-$5/2$ Fe$^{3+}$ cations. The negative $\theta$ indicates predominant AFM interactions in Bi$_4$Fe$_5$O$_{13}$F.

In fields of 0.1 T and higher (Fig. 7, bottom part), the most conspicuous effect is the double anomaly at $T_1 = 62$ K and $T_2 = 71$ K. In lower fields, a third anomaly around $T_N = 178$ K could be additionally observed (Fig. 7, top). Heat-capacity ($C_p$) measurements consistently show the anomalies at $T_1$, $T_2$, and $T_N$, thus confirming the intrinsic nature of these magnetic transitions (Fig. 7, inset). The anomalies at $T_1$ and $T_2$ are indicative of first-order transitions with small latent heats.

Considering the neutron diffraction data, we conclude that Bi$_4$Fe$_5$O$_{13}$F undergoes an antiferromagnetic ordering of the Fe moments at $T_N = 178$ K. However, this ordering is presumably incomplete, as shown by the large anomalies in the heat capacity at $T_1$ and $T_2$. The area under the heat-capacity curve...

plotted as $C_p/T$ vs $T$ corresponds to the entropy release upon a magnetic transition. The large amount of entropy released at $T_1$ and $T_2$ implies that above $T_1$ the system develops an incompletely ordered intermediate AFM structure, which is further altered at $T_2$ and eventually disappears at $T_N$. This peculiar behavior is independently confirmed by the drastic changes in the magnetic neutron scattering (Sec. III B).

D. Microscopic magnetic model

To elucidate relevant magnetic interactions, the band structure of Bi$_x$Fe$_5$O$_{13}$F was calculated. Regarding the band structure, this oxyfluoride is very similar to insulating Fe$^{3+}$ oxides. Its electronic spectrum (Fig. 9) reveals oxygen and fluorine 2$p$ bands between $-5$ eV and the Fermi level. The Fe 3$d$ bands are around $-6$ eV (filled) and at $+2$ eV (empty), with the splitting of 8 eV that roughly matches the on-site Coulomb repulsion of $U = 7$ eV. Bi 6$s$ orbitals form bonding states at around $-10$ eV.

In DFT + $U$ calculations, the energy gap of 1.5–2.0 eV depending on the spin configuration concurs with the brown color of Bi$_x$Fe$_5$O$_{13}$F. Magnetic moments of Fe atoms are about 4.6 $\mu_B$, which is larger than the experimental values of 4.06 (6) $\mu_B$ and 3.34 (6) $\mu_B$ for Fe$_1$, Fe$_3$, and Fe$_2$, respectively (see Table III). However, the direct comparison between the DFT + $U$ estimates and the experimental values from neutron diffraction is usually impossible, because DFT + $U$ does not account for the effect of antiferromagnetic spin fluctuations. For example, our reference calculations for NdFeO$_3$ yield similar magnetic moments of 4.5–4.7 $\mu_B$ (depending on the $U$ value) that likewise exceed the experimental value of 4.18 $\mu_B$ at 1.5 K.

Magnetic couplings extracted from the DFT + $U$ band structure indicate a predominant interaction $J_{d} = 191$ K within the Fe$_2$O$_7$ dimer, in agreement with the 180° Fe–O–Fe exchange pathway, which is most favorable for the AFM coupling, according to the Goodenough-Kanamori-Anderson rules. Other nearest-neighbor couplings are also AFM, but much weaker than $J_{d}$ according to the lower Fe–O–Fe angles (see Table IV). In general, the couplings decrease as the Fe–O–Fe angle approaches 90°, although this trend is violated at the lowest angles ($J_{c1} > J_{c2}$), where the direct Fe-Fe exchange comes into play. The couplings beyond nearest neighbors are all below 2 K and can be safely neglected in a first approximation. The resulting spin lattice has pentagonal-like

![FIG. 5. (Color online) Magnetic structure of Bi$_x$Fe$_5$O$_{13}$F at $T = 1.5$ K. denote the transition temperatures $T_1$, $T_2$, and $T_N$ (compare to Fig. 6).

Monte Carlo simulations, performed for the spin lattice depicted in the right panel of Fig. 1 and the $J_i$ parameters from Table IV, suggest that at low temperatures Bi$_4$Fe$_5$O$_{13}$F should be magnetically ordered. The ordering pattern can be extracted from the spin-spin correlations (Table IV), as explained in Ref. 30. The normalized correlation $\langle S_i S_j \rangle / S^2$ is the measure of cosine $\varphi$, where $\varphi$ is the angle between the magnetic moments. Negative normalized correlations approaching $-1$ indicate antiparallel magnetic moments within the Fe$_2$O$_7$ dimers (the interaction $J_d$) as well as between the neighboring Fe1 and Fe3 along the $c$ direction (the interaction $J_c$). Despite the sizable AFM coupling $J_c$ between the adjacent Fe1 sites along $c$, the moments on these Fe1 sites are parallel, as shown by the positive spin-spin correlation of nearly +1 (Table IV). In this way, the simulations identify the ferrimagnetic order within the rutile-like chains, in agreement with the experiment.

The Monte Carlo simulations also confirm the non-collinear ordering pattern in the $ab$ plane. The spin-spin correlations of $-0.81$ and $-0.84$ for $J_{ab1}$ and $J_{ab2}$, respectively, imply that the magnetic moments on the adjacent Fe1 and Fe2 sites form an angle of about $145^\circ$, in agreement with the roughly $135^\circ$ arrangement observed experimentally. Altogether, our microscopic model of magnetic interactions in Bi$_4$Fe$_5$O$_{13}$F is in excellent agreement with the experimental ground-state magnetic configuration.

The Monte Carlo simulations also confirm the non-collinear ordering pattern in the $ab$ plane. The spin-spin correlations of $-0.81$ and $-0.84$ for $J_{ab1}$ and $J_{ab2}$, respectively, imply that the magnetic moments on the adjacent Fe1 and Fe2 sites form an angle of about $145^\circ$, in agreement with the roughly $135^\circ$ arrangement observed experimentally. Altogether, our microscopic model of magnetic interactions in Bi$_4$Fe$_5$O$_{13}$F is in excellent agreement with the experimental ground-state magnetic configuration.

Following the expectations, the spin lattice of Bi$_4$Fe$_5$O$_{13}$F features pentagonal units with exclusively AFM interactions in the ground-state magnetic configuration. Indeed, in the ground-state magnetic structure only the strongest

![FIG. 7. (Color online) Magnetic susceptibility of Bi$_4$Fe$_5$O$_{13}$F measured in applied fields of 0.01, 0.5, and 5 T. The sizable field dependence is due to a tiny amount of ferromagnetic impurity. The inset shows the heat capacity divided by temperature ($C_p/T$). ![TABLE IV. Magnetic interactions in Bi$_4$Fe$_5$O$_{13}$F. The table lists Fe-Fe distances, Fe-O-Fe angles, exchange integrals $J_i$, as well as normalized spin-spin correlations $\langle S_i S_j \rangle / S^2$ in the ground-state magnetic configuration, as obtained from Monte Carlo simulations.](table1)
coupling $J_d$ is fully satisfied. The moments coupled by $J_{ab1}$ and $J_{ab2}$ develop the non-collinear configuration, whereas the AFM coupling $J_1$ is fully suppressed and gives way to the ferromagnetic (FM) order. The coupling $J_2$ is also fully satisfied, because it does not compete with any other interaction in this system.

The analysis of the Heisenberg Hamiltonian [Eq. (1)] determines the relative spin arrangement only. The arrangement of spins with respect to the crystallographic directions depends on magnetic anisotropy terms that should be addressed in future studies. While the planar spin arrangement is induced by the very nature of isotropic exchange couplings on the Cairo lattice, the location of spins in the $ab$ plane may be traced back to the tetragonal symmetry of the $Bi_4Fe_5O_{13}F$ structure.

IV. DISCUSSION AND SUMMARY

Our study puts forward $Bi_4Fe_5O_{13}F$ as an interesting material prototype of the Cairo pentagonal spin lattice. A comprehensive structural characterization reveals the robust tetragonal symmetry and only minor structural changes between 1.5 and 700 K. The rigid crystal structure ensures temperature-independent magnetic couplings and a reliable mapping of magnetic properties on the Cairo-lattice spin model.

Similar to $Bi_2Fe_4O_9$, $Bi_4Fe_5O_{13}F$ is not a perfect prototype of the Cairo spin lattice (Fig. 1). In $Bi_2Fe_4O_{13}F$, the leading AFM coupling $J_d$ stands for the coupling $J_1$, whereas two nonequivalent couplings $J_{ab1}$ and $J_{ab2}$ stand for the single coupling $J_2$. Additionally, the lattice is decorated by Fe dumbbells that replace all four-vertex sites. However, this kind of interaction is anticipated for this magnetic model. However, the magnetic order in $Bi_4Fe_5O_{13}F$ is altered. One plausible explanation is the formation of partially disordered AFM states that have higher entropy than the fully ordered non-collinear AFM structure. The partially disordered states are found in magnetic models based on triangular spin lattices. They are indeed observed in $Co^{2+}$ halides, such as CsCoCl$_3$ and RbCoBr$_3$. Surprisingly, our experimental results may put forward similar physics on the pentagonal spin lattice.

Microscopically, the main difference between $Bi_2Fe_4O_9$ and $Bi_4Fe_5O_{13}F$ pertains to the stacking of the pentagonal layers. While in $Bi_2Fe_4O_9$ these layers are directly stacked on top of each other, $Bi_4Fe_5O_{13}F$ features additional Fe3 sites between the pentagonal layers. The voids formed between the Fe3O$_6$ octahedra are filled with the $Bi_4$ tetrahedra that stabilize the modified crystal structure. One can also devise more complex stacking sequences and expand the family of materials with Cairo spin lattices. Although the change in the stacking sequence has no direct influence on the in-plane physics, the distance between the pentagonal layers affects the dimensionality of the spin system. Additionally, even weak structural changes have strong effect on the magnetism, as shown by the tangible difference in the magnetic behavior of $Bi_4Fe_5O_{13}F$ and $Bi_2Fe_4O_9$. We hope that our study will stimulate further theoretical work on both Cairo-lattice compounds available so far. A detailed experimental investigation of intricate magnetic transitions in $Bi_4Fe_5O_{13}F$ will also be insightful.

In summary, $Bi_4Fe_5O_{13}F$ is an interesting material prototype of the frustrated Cairo spin lattice. At low temperatures, $Bi_4Fe_5O_{13}F$ develops non-collinear antiferromagnetic order, which is anticipated for this magnetic model. However, the magnetic ordering is strongly altered at $T_1 \approx 62$ K and $T_2 \approx 71$ K, even though the crystal structure is virtually unchanged. The transitions at $T_1$ and $T_2$ also involve a sizable increase in the magnetic entropy that may be tentatively ascribed to the transformation toward partially disordered antiferromagnetic states.
